Abstract. Big Bang Nucleosynthesis (BBN) and the Cosmic Background Radiation (CBR) provide complementary probes of the early evolution of the Universe and of its particle content. Neutrinos play important roles in both cases, influencing the primordial abundances of the nuclides produced by BBN during the first 20 minutes as well as the spectrum of temperature fluctuations imprinted on the CBR when the Universe is some 400 thousand years old. In this talk I review the physical effects of neutrinos at these different epochs in the evolution of the Universe and compare the theoretical predictions with the observational data to explore the consistency of the standard models of cosmology and particle physics and to constrain neutrino physics as well as more general, beyond-the-standard-model physics.

1. Introduction

The Universe is expanding and is filled with radiation. All wavelengths (*e.g.*, of photons as well as the deBroglie wavelengths of freely expanding massive particles) are stretched along with the expansion. As a result, during its earlier evolution the Universe was hot and dense. The combination of high temperature (energy) and density ensures that the collision rate among particles is very high during very early epochs, guaranteeing that all particles, with the possible exception of those with gravitational strength interactions, were in equilibrium at sufficiently early times. As the early Universe expands and cools, interaction rates decline and, depending on the strength of their interactions, different particles fall out of equilibrium at different epochs. For neutrinos (the standard, “active” neutrinos ν_e, ν_μ, ν_τ) the departure from equilibrium occurs when the Universe is a few tenths of a second old and the temperature of the CBR photons, $e^\pm$ pairs, and the neutrinos is a few MeV. It should be noted that departure from equilibrium is not sharp and collisions continue to occur; for $T \lesssim 2 - 3$ MeV, the neutrino interaction rates become slower than the universal expansion rate (as measured by the Hubble parameter H) and the neutrinos effectively decouple from the CBR photons and the $e^\pm$ pairs present at that time. However, electron neutrinos (and antineutrinos) continue to interact with the baryons (nucleons) via the charged-current, weak interactions until the Universe is a few seconds old and the temperature has dropped below an MeV. Once again, this decoupling is not abrupt (the neutrinos do *not* “freeze-out”) and two body reactions among neutrons, protons, $e^\pm$ pairs and $\nu_e(\bar{\nu}_e)$ continue to influence the ratio of neutrons to protons, albeit not sufficiently rapidly to permit the ratio to track its equilibrium value of $n/p = \exp(-\Delta m/T)$, where $\Delta m = m_n - m_p = 1.29$ MeV. As a result, the n/p ratio decreases from $\sim 1/6$ at

“freeze-out” to $\sim 1/7$ when BBN begins at ~ 200 sec ($T \approx 80$ keV). Since the neutrinos are extremely relativistic during these epochs, they can influence BBN in several ways. The standard cosmology, universal expansion rate is determined through the Friedman equation by the total energy density which, during these early epochs, is dominated by massless particles along with those massive particles which are extremely relativistic: CBR photons, $e^\pm$ pairs, neutrinos. The early Universe is “radiation” dominated and neutrinos are a significant component of the “radiation”. In addition, through their charged-current weak interactions the electron-type neutrinos help to control the neutron-to-proton ratio, effectively limiting the primordial abundance of ^4He . Furthermore, if there is a lepton asymmetry (*e.g.*, more ν_e than $\bar{\nu}_e$ or, vice-versa), much larger than the universal baryon asymmetry, the weak rates interconverting neutrons and protons would be affected as well.

Although $e^\pm$ pairs annihilated during the first few seconds, the surviving electrons (equal in number to the protons to ensure charge neutrality) and the CBR photons interact electromagnetically, tying the photons to the electrons (via Compton scattering). Only after the electrons and nuclides (mainly protons and alphas) combine to form neutral atoms (“recombination”) are the CBR photons released from the tyranny of the electrons to become freely propagating. This occurs when the Universe is some 400 thousand years old and the relic photons, redshifted to the currently observed black body radiation at $T = 2.725\text{K}$, bring us a snapshot of the universe at this early epoch. At this relatively late stage in the early evolution of the Universe, the key role of the freely propagating, relativistic neutrinos is in contributing to the total radiation density, determining the universal expansion rate (*e.g.*, the time – temperature relation). It should be noted that if the neutrino masses are sufficiently large the neutrinos will have become nonrelativistic and their free-streaming, at $v < c$, has the potential to damp density fluctuations in the baryon fluid. This important topic, which is not addressed here, was covered by Scott Dodelson in his talk; the interested reader is directed to his contribution to this volume.

The primordial abundances of the relic nuclei produced during BBN depend on the baryon (nucleon) density and on the early-Universe expansion rate. The amplitudes and angular distribution of the CBR temperature fluctuations also depend on these same parameters (as well as on several others). The universal abundance of baryons may be quantified by comparing the number of baryons (nucleons) to the number of CBR photons,

$$\eta_{10} \equiv 10^{10}(n_{\text{B}}/n_{\gamma}). \quad (1)$$

As the Universe expands the densities of baryons and photons decrease but the numbers of baryons and of CBR photons in a comoving volume are unchanged (post- $e^\pm$ annihilation) so that η_{10} measured at present, at BBN, and at recombination should all be the same. This is one of the key cosmological tests. Since the baryon mass density ($\rho_{\text{B}} \equiv \Omega_{\text{B}}\rho_c$, where $\rho_c = 3H_0^2/8\pi G$ is the present critical mass density) plays a direct role in the growth of perturbations, it is convenient to quantify the baryon abundance using a combination of Ω_{B} and h , the present value of the Hubble parameter (H_0) measured in units of $100 \text{ kms}^{-1}\text{Mpc}^{-1}$,

$$\eta_{10} = 274 \omega_{\text{B}} \equiv 274 \Omega_{\text{B}} h^2. \quad (2)$$

The Hubble parameter, $H = H(t)$, measures the expansion rate of the Universe. Deviations from the standard model ($H \rightarrow H'$) may be parameterized by an expansion rate parameter $S \equiv H'/H$. Since in the standard model H is determined by the energy density in relativistic particles, deviations from the standard cosmology ($S \neq 1$) may also be quantified by the “equivalent number of neutrinos” $\Delta N_\nu \equiv N_\nu - 3$. Prior to $e^\pm$ annihilation, these two parameters are related by

$$S = (1 + 7\Delta N_\nu/43)^{1/2}. \quad (3)$$

Note that ΔN_ν is a convenient way to quantify *any* deviation from the standard model expansion rate and is not necessarily related to extra (or fewer!) neutrinos.

The question to be addressed here is, “Are the predictions and observations of the baryon density and expansion rate of the Universe at 20 minutes (BBN) and 400 thousand years (CBR) in agreement with each other and with the standard models of cosmology and particle physics?”. If yes, what constraints are there on beyond-the-standard-model models? Given the limited space allocated to this article, only the current status of this quest is summarized here. The reader will find more detail and further references in my recent review article [1].

2. The Universe At 20 Minutes: BBN

Nuclear reactions among neutrons and protons occur at large rates during the early evolution of the Universe but until the Universe has cooled sufficiently ($T \lesssim 80$ keV, $t \gtrsim 3$ minutes), they fail to yield significant abundances of complex nuclides because of their competition with photo-destruction reactions involving the enormously more numerous CBR photons (gamma-rays). Once BBN begins the available neutrons are consumed very quickly to build ^4He and all further nucleosynthesis among electrically charged nuclides (H, D, T, ^3He , ^4He) involves reactions which become Coulomb-suppressed as the Universe expands and cools. As a result BBN terminates when $T \lesssim 30$ keV ($t \gtrsim 25$ min). In the first ~ 20 minutes of its evolution the cosmic nuclear reactor produces (in astrophysically interesting abundances) deuterium, helium-3 (any tritium decays to ^3He), helium-4 and, because of the gaps at mass-5 and mass-8, only a trace amount of lithium-7 (produced mainly as beryllium-7 which, later in the evolution captures an electron and decays to ^7Li).

Of the light nuclides produced during BBN, the abundances of D, ^3He , and ^7Li are determined by the competition between two body production and destruction rates which are dependent on the overall density of baryons. As a result, these nuclides are all potential baryometers. Of these, D is the baryometer of choice since its post-BBN evolution is simple (D is only destroyed, burned to ^3He and beyond, when gas is incorporated into stars) and the BBN-predicted abundance is a relatively sensitive function of the baryon density ($\text{D}/\text{H} \propto \eta_{10}^{-1.6}$). In contrast, the primordial abundance of ^4He is relatively insensitive to the baryon density, depending mainly on the abundance of neutrons when BBN begins. The ^4He relic abundance is usually expressed as a “mass fraction” $Y_{\text{P}} \equiv 4y/(1 + 4y)$, where $y \equiv n_{\text{He}}/n_{\text{H}}$ (since this *assumes* $m_{\text{He}}/m_{\text{H}} = 4$, Y_{P} is *not* the true helium mass fraction). Since the expansion rate (S), in combination with the rate of the charged-current weak interactions, plays an important role in regulating the pre-BBN neutron to proton ratio, Y_{P} is sensitive to S . As shown by the D and ^4He isoabundance curves in Figure 1, deuterium and helium-4 provide complementary probes of the universal baryon density and expansion rate.

While most models of particle physics beyond the standard model adopt (or impose) a lepton asymmetry of the same order of magnitude as the (very small!) baryon asymmetry ($\sim 10^{-10}\eta_{10}$), lepton (neutrino) asymmetries orders of magnitude larger are currently not excluded by any experimental data. In analogy with η_{10} which measures the baryon asymmetry, the lepton (neutrino) asymmetry, $L = L_\nu \equiv \sum_\alpha L_{\nu_\alpha}$, may be quantified by the ratios of the neutral lepton chemical potentials ($\alpha \equiv e, \mu, \tau$) to the temperature (in energy units) $\xi_{\nu_\alpha} \equiv \mu_{\nu_\alpha}/kT$, where

$$L_{\nu_\alpha} \equiv \left(\frac{n_{\nu_\alpha} - n_{\bar{\nu}_\alpha}}{n_\gamma} \right) = \frac{\pi^2}{12\zeta(3)} \left(\frac{T_{\nu_\alpha}}{T_\gamma} \right)^3 \left(\xi_{\nu_\alpha} + \frac{\xi_{\nu_\alpha}^3}{\pi^2} \right). \quad (4)$$

Although any neutrino degeneracy always *increases* the energy density in the neutrinos, resulting in an *effective* $\Delta N_\nu > 0$, the range of $|\xi|$ of interest to BBN is limited to sufficiently small values that the increase in S due to a non-zero ξ is negligible. However, a small asymmetry between *electron* type neutrinos and antineutrinos ($|\xi_e| \gtrsim 10^{-2}$; $|L| \gtrsim 0.007$), while large compared to the

Figure 1. Isoabundance curves for Deuterium (dashed lines) and Helium-4 (solid lines) in the expansion rate factor (S) – baryon abundance (η_{10}) plane. The ${}^4\text{He}$ curves, from bottom to top, are for $Y_P = 0.23, 0.24, 0.25$. The D curves, from left to right, are for $y_D = 4.0, 3.0, 2.0$.

Figure 2. Isoabundance curves for Deuterium (dashed lines) and Helium-4 (solid lines) in the neutrino asymmetry (ξ_e) – baryon abundance (η_{10}) plane. The ${}^4\text{He}$ curves, from bottom to top, are for $Y_P = 0.25, 0.24, 0.23$. The D curves, from left to right, are for $y_D = 4.0, 3.0, 2.0$.

baryon asymmetry, can have a significant impact on BBN by modifying the pre-BBN neutron to proton ratio. The corresponding D and ${}^4\text{He}$ isoabundance curves in the $\xi_e - \eta_{10}$ plane are shown in Figure 2.

For restricted but interestingly large ranges of $\eta_{10}(\omega_B)$, $\Delta N_\nu(S)$, and ξ_e , Kneller and Steigman [2] found simple but accurate fits to the BBN-predicted abundances of the light nuclides. For D ($y_D \equiv 10^5(\text{D}/\text{H})$) and ${}^4\text{He}$ (Y_P), these are

$$y_D \equiv 46.5(1 \pm 0.03)\eta_D^{-1.6} ; \quad Y_P \equiv (0.2384 \pm 0.0006) + \eta_{\text{He}}/625, \quad (5)$$

where

$$\eta_D = \eta_{10} - 6(S - 1) + \frac{5\xi_e}{4} ; \quad \eta_{\text{He}} = \eta_{10} + 100(S - 1) - \frac{575\xi_e}{4}. \quad (6)$$

2.1. Observed Relic Abundances

Although there are observations of deuterium in the solar system and the interstellar medium (ISM) of the Galaxy which provide interesting *lower* bounds to its primordial abundance, it is observations of relic D in a few (too few!), high redshift, low metallicity, QSO absorption line systems (QSOALS) which are of most value in enabling estimates of the primordial abundance. The identical absorption spectra of D I and H I (modulo the velocity/wavelength shift resulting from the heavier reduced mass of the deuterium atom) is a liability, limiting the number of useful targets in the vast Lyman-alpha forest of QSO absorption spectra (see, *e.g.*, Kirkman *et al.* [3] for further discussion). Through 2003 there were only five QSOALS with deuterium detections leading to reasonably reliable abundance determinations [3] (and references therein); these, including a very recent sixth determination by O’Meara *et al.* [4], are shown in Figure 3. Also shown for comparison are the solar system and ISM D abundances. There is clearly excessive

dispersion among the low metallicity D abundances which tends to mask the anticipated primordial deuterium plateau, suggesting that systematic errors, whose magnitudes are hard to estimate, may have contaminated the determinations of at least some of the D I and/or H I column densities. Despite these concerns, the best that can be done with the present data is to identify the relic deuterium abundance with the weighted mean of the high- z , low- Z D/H ratios: $y_D \equiv 2.68^{+0.27}_{-0.25}$, corresponding to $\eta_D = 5.95^{+0.36}_{-0.39}$ (see eq. 5).

Figure 3. Observationally inferred deuterium abundances versus metallicity for six high redshift, low metallicity QSOALS (filled circles). Also shown are the abundances derived for the pre-solar nebula (Sun) and for the local interstellar medium (ISM).

Figure 4. The OS-derived ^4He versus oxygen abundances for 7 low metallicity H II regions from IT and one higher metallicity H II region from Peimbert *et al.* (filled circles). The horizontal line shows the weighted mean of the 8 helium abundances.

The post-BBN evolution of ^4He is also quite simple. As gas cycles through generations of stars, hydrogen is burned to helium-4 (and beyond), increasing the ^4He abundance above its primordial value. Therefore the present ^4He mass fraction, Y_0 , has received a significant contribution from post-BBN, stellar nucleosynthesis, and $Y_0 > Y_P$. However, since the “metals” such as oxygen are produced by short-lived, massive stars and ^4He is synthesized (to a greater or lesser extent) by all stars, at very low metallicity the increase in Y should lag that in, *e.g.*, O/H , so that as $\text{O}/\text{H} \rightarrow 0$, $Y \rightarrow Y_P$. Therefore, although ^4He is observed in the Sun and in Galactic H II regions, the key data for inferring its primordial abundance are provided by observations of helium and hydrogen emission (recombination) lines from low-metallicity, extragalactic H II regions. The present inventory of such regions studied for their helium content exceeds 80 (see Izotov & Thuan (IT) [5]). Since for such a large data set even modest observational errors for the individual H II regions can lead to an inferred primordial abundance whose *formal* statistical uncertainty is very small, special care must be taken to include hitherto ignored systematic corrections and/or errors. It is the general consensus that the present uncertainty in Y_P is dominated by the latter, rather than by the former errors. However, attempts to include estimates of them have often been unsystematic or absent. To account for some of these uncertainties, Olive, Steigman, and Walker [6] followed the Fields and Olive [7] analysis to estimate a $\sim 95\%$ confidence range of $0.228 \leq Y_P \leq 0.248$ (for $Y_P = 0.238 \pm 0.005$, this corresponds to $\eta_{\text{He}} = -0.25 \pm 3.15$; see eq. 5).

The most systematic analysis to date is that of the IT data by Olive & Skillman 2004 (OS) [8]. Using criteria outlined in their earlier paper [8], OS examined the IT data set and decided they could apply their analysis to only 7 of the 82 IT H II regions. This tiny data set, combined with its limited range in oxygen abundance, severely limits the statistical significance of the OS conclusions. In Figure 4 are shown the OS-inferred helium abundances from the IT data set and from one, higher metallicity H II region observed by Peimbert *et al.* [9]. From these eight H II regions alone there is no evidence that the helium abundance is correlated with the oxygen abundance; the weighted mean is $\langle Y \rangle = 0.250 \pm 0.002$, leading to a robust $\sim 2\sigma$ upper bound on the primordial helium abundance of $Y_P \leq 0.254$ (corresponding to $\eta_{\text{He}} \leq 9.75$).

2.2. Comparison Between BBN-Predicted And Observed Relic Abundances

Figure 5. Isoabundance curves for Deuterium (dashed lines) and Helium-4 (solid lines) in the expansion rate factor – baryon abundance plane (see Fig. 1). The filled circle and error bars correspond to the adopted relic abundances.

Figure 6. Isoabundance curves for Deuterium (dashed lines) and Helium-4 (solid lines) in the neutrino asymmetry – baryon abundance plane (see Fig. 2). The filled circle and error bars correspond to the adopted relic abundances.

The relic abundances adopted here correspond to $\eta_D = 5.95^{+0.36}_{-0.39}$ and $\eta_{\text{He}} = -0.25 \pm 3.15$. In the absence of a large lepton asymmetry ($\xi_e \ll 1$), this implies $S = 0.942 \pm 0.030$ ($N_\nu = 2.30^{+0.35}_{-0.34}$) and $\eta_{10} = 5.60^{+0.38}_{-0.41}$ ($\Omega_B h^2 = 0.0204^{+0.0014}_{-0.0015}$). This is consistent with the standard model ($S = 1$, $N_\nu = 3$) at $\sim 2\sigma$ (see Figure 5). For the standard expansion rate/particle content ($S = 1$, $N_\nu = 3$), the inferred values of η_D and η_{He} result in $\xi_e = 0.043 \pm 0.022$ and $\eta_{10} = 5.90^{+0.36}_{-0.39}$ ($\Omega_B h^2 = 0.0215^{+0.0013}_{-0.0014}$). At $\sim 2\sigma$, this is consistent with no lepton asymmetry ($\xi_e = 0$; see Figure 6). The confrontation of the BBN predictions with the relic abundance observations of D and ^4He reveals internal consistency (at $\lesssim 2\sigma$) of the standard models of particle physics ($N_\nu = 3$, $\xi_e = 0$) and cosmology ($S = 1$) and it fixes the baryon abundance to an accuracy of $\sim 7\%$ during the first few minutes of the evolution of the Universe. At the same time this comparison sets constraints on possible deviations from these standard models (*e.g.*, $N_\nu \neq 4$). How do these BBN results compare with what the CBR reveals about the Universe some 400 thousand years later?

3. Confrontation With The CBR

The angular spectrum of CBR temperature fluctuations depends on several key cosmological parameters, including the baryon density and the relativistic energy density (for further discussion and references, see Hu and Dodelson 2002 [10] and Barger *et al.* 2003 [11]), thereby providing a probe of η_{10} and N_ν some 400 kyr after BBN. However, the CBR temperature fluctuation spectrum is blind to any sufficiently small lepton asymmetry $|\xi_e| \ll 1$. With N_ν allowed to depart from the standard model value, Barger *et al.* [11] found the first year WMAP data [12] is best fit by $\Omega_B h^2 = 0.0230$ and $N_\nu = 2.75$, in excellent agreement with the purely BBN results above. In fact, the CBR is a much better baryometer than it is a chronometer, so that while the 2σ range for the baryon density is limited to $0.0204 \leq \Omega_B h^2 \leq 0.0265$, the corresponding 2σ range for N_ν was found to be $0.9 \leq N_\nu \leq 8.3$ [11].

Quite recently the WMAP team released (and analyzed) their 3-year data. For $N_\nu = 3$, Spergel *et al.* 2006 [13] find $\Omega_B h^2 = 0.0223^{+0.0007}_{-0.0009}$. When N_ν is free to vary, V. Simha and the current author, in very preliminary work in progress, find a similar result for the baryon density (not unexpected since in fitting the CBR data the baryon density and the relativistic energy density are largely uncorrelated), $\Omega_B h^2 = 0.0222 \pm 0.0007$, along with a 2σ range for N_ν which is virtually unchanged from the previous WMAP-based result [11]: $2.1 \leq N_\nu \leq 8.3$. However, this latter result, and those of Spergel *et al.* 2006 and Seljak, Slosar, and McDonald 2006 [13] are not in very good agreement with each other and until the differences are fully understood, this constraint should be regarded with a very large grain of salt.

4. Summary

Comparison between the BBN predictions and relic abundance observations of deuterium and helium-4 reveals consistency with the standard models of particle physics and cosmology and constrains the value of the baryon abundance during the first few minutes of the evolution of the Universe. This comparison also enables quantitative constraints on possible deviations from these standard models, particularly in the neutrino sector. Some 400 thousand years later, when the CBR photons are set free, the angular spectrum of temperature fluctuations encodes information about several key cosmological parameters, including N_ν and the baryon density. The present data reveal consistency (at $\sim 2\sigma$) between the values of $\Omega_B h^2$ and N_ν inferred from the first few minutes of the evolution of the Universe and from a snapshot of the Universe some 400 kyr later. While there is room for surprises, at present the standard models appear robust.
